What Is Congenital Hip Dislocation?

- It is a condition in which the ball joint at the top of the leg does not sit in the correct position in the hip joint causing potential dislocation of the thigh bone from the socket in the pelvis.

Signs and Symptoms

- Limited movement of the flexed hip
- Shortening of one leg
- Waddling when walking
- May only be found on physical exam by pediatrician who checks for hip stability

What is the cause?

- Position of infant before birth combined with lax joints may result in incomplete formation of hip joint.
- Breech Birth (infant born feet first)
- More common in girls and first born babies
- Family history of congenital hip dislocation

Is there any treatment?

- Treatment is performed with a special brace such as a Pavlik harness. This holds the infant’s hips in a position that allows the joint to develop in the right position and stabilize.
- If this does not work, a “closed reduction” in which the hip is put back in place without surgery, may be needed.
- If the closed reduction does not work, or if there is a dislocation in an older child, surgery is needed to reduce the hip joint into proper position.
